THE NON CANDIDATE CONSTRAINT METHOD
FOR REDUCING THE SIZE OF A LINEAR PROGRAM

by

Awanti P. Sethi and Gerald L. Thompson

ABSTRACT

A non candidate constraint in a linear program is one which never contains a pivot element during the course of solving the problem. Discovering non candidate constraints is computationally costly since their discovery, in general, depends on the actual sequence of pivots used. Knowing which constraints are non candidate is of great computational benefit since they need not be kept in updated form. Our experience indicates that from 50 to 80 percent of the constraints in randomly problems are non candidates at least part of the time.

In this paper we present a "learning" approach to the identification of non candidate constraints. At each iteration we determine which constraints can potentially be pivotal; these are candidate constraints and all others are non candidate constraints on that step. On proceeding with the simplex method we update only the candidate constraints. If a non candidate constraint becomes candidate on a later step, we update it and add it to the candidate list.

Although the constant checking of constraints to see whether they are changing from being candidate to non candidate is computationally costly, we obtain the computational benefit of having to keep in updated form a much smaller tableau.

The net benefit of using this strategy is positive and results in a 25 to 50 percent reduction in total computation time. This paper describes the method in detail and gives computational results of testing it on a series of randomly generated problems.

THE NON CANDIDATE CONSTRAINT METHOD
FOR REDUCING THE SIZE OF A LINEAR PROGRAM

by

Awanti P. Sethi and Gerald L. Thompson

1. Introduction.

Thompson, Tonge, and Zionts [4,6] defined a redundant constraint in a linear programming problem as one which could be dropped without changing the primal constraint set. Most linear programs have some redundant constraints, and it would be desirable to be able to identify them. However, the discovery of redundant constraints is computationally extremely costly.

A much weaker concept is that of a non-candidate constraint, to be defined precisely in Section 2. Intuitively a permanently non-candidate constraint is one which never becomes pivotal, that is, never contains a pivot element, during the course of solving a given linear program. Such constraints may, but need not, be redundant in the strong sense of [4]. But they are never used during the course of solving a problem, so that keeping them in updated form is of no value.

The discovery of permanently non candidate constraints is computationally even more difficult than the discovery of redundant constraints, since, in general, they depend on the choice of a specific sequence of pivots. However, we have found that from 50 to 80 percent of the constraints in randomly generated problems are sometimes non candidate constraints, see Section 4, so that their discovery can be of great computational benefit.

In this paper we present a "learning" approach to the identification of non candidate constraints. At each iteration we determine which constraints can potentially be pivotal; these are the candidate constraints; all others are non candidate constraints on that step. In proceeding with the simplex iterations

we update only candidate constraints, on the assumption that non candidate constraints on that step won't become candidates later. In case an error is made, and a previously non candidate becomes a candidate constraint on a later iteration, we update it, and add it to the candidate list.

Although the constant checking of constraints to see if they are changing from being candidate to non candidate constraints or vice versa is costly, there is the computational benefit of having a much smaller tableau to update at each pivot. The net benefit of using this strategy is positive and results in 25-50 percent reduction in total computation time, see Section 4.

2. Basis for the Method.

The non candidate constraint method is merely a modification of the standard simplex method, no new theoretical results are needed to establish the correctness of the approach. In order to explain it we set up some standard linear programming terminology.

Consider a linear programming problem stated form

$$\begin{aligned} &\text{Maximize } \{z = cx\} \\ &\text{Subject to } Ax = b \\ &\quad x \geq 0 \end{aligned} \tag{1}$$

where A is $m \times n$, b is $m \times 1$, c is $1 \times n$, and x is $n \times 1$. We assume slack variables have been included in the definition of A , and that the problem has been transformed (by well-known techniques) so that $b \geq 0$. The simplex tableau at the k th iteration is denoted by

| | |
|-----------|-----------|
| $A^{(k)}$ | $b^{(k)}$ |
| $c^{(k)}$ | $z^{(k)}$ |

(2)

where initially

$$A^{(0)} = A, \quad b^{(0)} = b, \quad c^{(0)} = -c, \quad z^{(0)} = 0. \quad (3)$$

We define the following sets of indices

$$I = \{1, \dots, m\} \quad (4)$$

$$J = \{1, \dots, n\} \quad (5)$$

$$J^{(k)} = \{j \mid j \in J \text{ and } c_j^{(k)} < 0\} \quad (6)$$

$$R_j^{(k)} = \{i \mid i \in I \text{ and } \frac{b_i^{(k)}}{a_{ij}^{(k)}} = \underset{a_{hj}^{(k)} > 0}{\text{Minimum}} \frac{b_h^{(k)}}{a_{hj}^{(k)}}\} \quad (7)$$

Clearly, $J^{(k)}$ is the set of indices of potential incoming variables at step k , while $R_j^{(k)}$ is the set of potential outgoing rows if column j is chosen to come in.

We can now define the set of candidate constraints at iteration k as

$$S^{(k)} = \{i \mid i \in R_j^{(k)} \text{ for some } j \in J^{(k)}\}. \quad (8)$$

The set of non candidate constraints at iteration (k) is then obviously

$$I - S^{(k)}. \quad (9)$$

In this paper we will use the maximum objective change rule [3, 5], which we will call the maximum z-change rule. To find it we calculate

$$\delta^{(k)} = \underset{j \in J^{(k)}, i \in R_j^{(k)}}{\text{Maximum}} \left(\frac{b_i^{(k)}}{a_{ij}^{(k)}} \right) (-c_j^{(k)}) \quad (10)$$

and determine the indices of the incoming variable j and outgoing variable i so that (1) holds and then

$$z^{(k+1)} = z^{(k)} + \delta^{(k)}. \quad (11)$$

Although a large amount of time is needed to determine the pivot giving the maximum z -change, a net improvement in computational performance has been found when it is used to solve moderate sized problems [5]. In this paper we will show that still further improvements can be obtained by using the maximum z -change rule in conjunction with the non candidate method.

By a partial pivot for a given choice of pivot row i and pivot column j , we shall mean the calculation of the updated right hand sides $b^{(k+1)}$ from $b^{(k)}$. We will say that constraint i is violated if $b_i^{(k+1)} < 0$. Because of the choice of pivot row i by the minimum ratio rule (7) and (10), it is clear that no non candidate constraint at step k is ever violated at step $k+1$ that is,

$$b_i^{(k+1)} \geq 0 \quad \text{for} \quad i \in I - S^{(k)}. \quad (12)$$

However a constraint which is a non candidate at step k could be violated at step $k+2, k+3, \dots$.

In the non candidate method described in the next section, the simplex tableau is updated at iteration k only for the constraints which are candidate at iteration k . Since from 50 to 80 percent of all constraints in randomly generated problems are non candidate, this results in considerable computational savings, see Section 4.

3. The Non Candidate Algorithm.

The flow chart for the non candidate simplex algorithm is shown in Figure 1. The initialization steps of finding the set $S^{(0)}$ of candidate constraints and the first maximum z -change pivot are given in boxes 1 and 2. They can be completed by making one pass through the original data of the problem. Step 3 is the pivot

step which updates the rows of the simplex tableau restricted to the candidate constraints. The rows corresponding to the non candidate constraints are not updated. In box 4 a test is made to see if the current tableau is optimal; if it is the algorithm stops; otherwise it continues.

In box 5 of Figure 1, the computer is instructed to make one pass through the updated tableau at the k th step which is restricted to the rows in $S^{(k)}$; during the data pass all non candidate constraints are removed from $S^{(k)}$ to form the set $S^{(k+1)}$. During this data pass it is possible to also carry out the instruction in box 6 of finding the maximum z -change pivot in the tableau restricted to $S^{(k+1)}$.

In box 7, the computer is instructed to perform a partial pivot on $b^{(k)}$ restricted to the set $S^{(k+1)}$; at the end of the partial pivot $b^{(k+1)}$ restricted to the same set and hence $x^{(k+1)}$ will be available. As instructed in box 8, the proposed solution, $x^{(k+1)}$, is then substituted into the non candidate constraints in the set $I - S^{(k)}$ to see if any of them is violated. If any such constraint is found to be violated, the computer is instructed in box 9 to update that constraint, and then go to box 5 to try again to find a maximum z -pivot and a new $x^{(k+1)}$. This process is repeated until eventually a proposed $x^{(k+1)}$ will be found which does not violate any non candidate constraint. When this happens, the computer goes from box 8 to box 10 where k is updated; and from there it goes back to box 3 to continue with the pivoting process.

Since the algorithm outlined is simply a reorganization of the standard simplex method, all of the anti-cycling techniques, and finiteness proofs for the latter hold for the non candidate method as well.

4. Computational Experience.

Table 1 gives the time comparison between the non candidate greatest z -change method and the greatest z -change method in solving a series of 19

randomly generated problems with two different densities of problem data. Since the same entry criterion was used in each method the sequence of pivots was identical in each. Hence the differences in solution times can be attributed entirely to the relative efficiencies of the two methods. We found that the non candidate method is more effective on problems with higher density, and also on larger problems.

Table 2 gives a computational comparison of the non candidate method and the ordinary simplex method on two sets of randomly generated problems. Note that the number of iterations is smaller for the non candidate method due to its greatest z-change entry criterion. The ratio of times for the two methods are close to the ratio of number of iterations, which indicates that the savings in time from not updating non candidate constraints approximates the additional time needed for the greatest z-change calculations.

We have so far not tried to compare the two methods on actual problems derived from real applications. However, the results so far on these randomly generated problems are very encouraging.

5. Variations and Extensions of the Method.

Many variants of the method described in this paper have occurred to us which we have not yet had time to test. We discuss some of them here.

(a) Connections with the GUB Method. The generalized upper bound (GUB) [6] method handles constraints which are sums of variables outside of the tableau. Usually such GUB constraints are also non candidate in our sense. When they are candidate constraints and are actually chosen to be pivotal, they are not re-introduced into the tableau as we do; instead special pivoting rules are added to the simplex algorithm. Perhaps such special pivoting rules could be extended to more general kinds of constraints.

(b) Intermittent candidate checking. Instead of checking for candidate constraints at each iteration as we do in box 5 of Figure 1, we could instead, perform this check only once every s th iteration, $s = 5$, say, where the danger is that a constraint could then become violated, and dual feasibility lost. This could be corrected by performing some dual pivots. In this way the method could become a kind of primal-dual algorithm. Only actual computational tests could show whether, and for what values of s , this method would be good.

(c) Extension to large problems. Most large linear programming problems are very sparse initially, but the tableau can fill in during the course of the computation. Hence the non candidate method is a potentially valuable way of keeping down the size of the working tableau, and/or the size of the basis inverse matrix. The difficulty is in performing the check for candidate constraints. To this end we propose that the original data be stored on two tapes, once in row order, and once in column order. Then the tape with row ordered data is used to check for candidates, and the tape with column ordered data used to check for incoming variables. We believe that the computations could be organized so that both of these steps could be done efficiently. If the number of candidate constraints is as small as we found in Table 2, then dramatic improvements in the solution of large linear programs might be possible using this method.

6. Conclusions.

In this paper we have defined the concept of candidate and non candidate constraints, and have demonstrated computationally that a modification of the simplex method can be made to take advantage of the fact that non candidate constraints need not be updated. The method assumes that a non candidate constraints at step k will remain so. If an error is made and such a constraint becomes a candidate at a later step then the constraint is updated and put back

into the tableau. Significant computational savings are possible by using this method. Extensions of the method to find the solution to large problems were sketched.

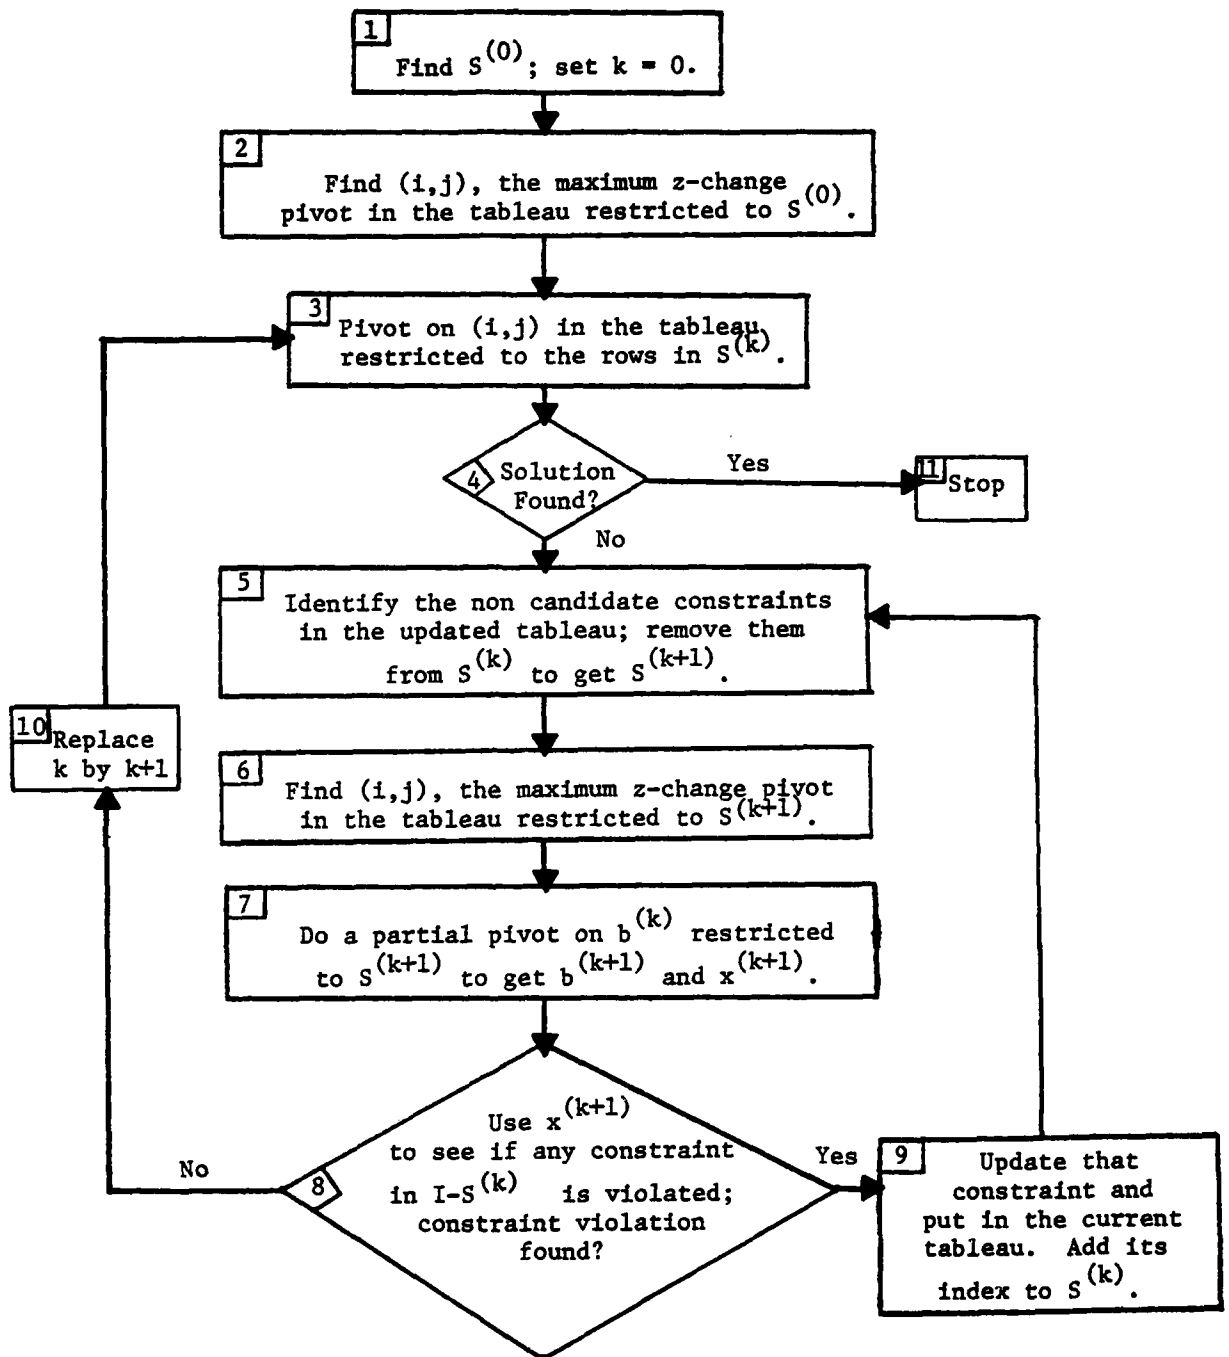

Figure 1. Flow chart for non candidate simplex algorithm.

| Rows | Columns | Greatest z-change non candidate Time (Secs) | Greatest z-change simplex Time (Secs) | Ratio of Times |
